Statistical learning theory: Theoretical guarantee for learning from limited data

- What is the test performance of a classifier with a particular training performance?
- How far is a classifier from the best performance model?
- How many training instances are needed to achieve a particular test performance?

Error Bounds

True risk and empirical risk: We are interested in true risk but can access only to empirical risk

- Training dataset $\{(x^{(1)}, y^{(1)}), ..., (x^{(N)}, y^{(N)})\}$ is sampled from P in an i.i.d manner
 - $-y^{(i)} \in \{+1, -1\}$: Binary classification
 - We want to estimate $f: X \rightarrow \{+1, -1\}$

Indicator function (0-1 loss)

- (True) risk: $R(f) = \Pr(f(x) \neq y) = E_{(x,y)\sim P} \left[1_{f(x)\neq y}^{p}\right]$
 - We cannot directly evaluate this since we do not know P
- Empirical risk: $R_N(f) = \frac{1}{N} \sum_{i=1}^N 1_{f(x^{(i)}) \neq y^{(i)}}$
 - Usually we estimate a classifier that minimizes this

Our goal: How good is the classifier learned by empirical risk minimization?

- Ultimate goal: find the best f in function class \mathcal{F}
 - Best function: $f^* = \operatorname{argmin}_{f \in \mathcal{F}} R(f)^{\text{True risk}}$
- Instead, empirical risk minimization: $f_N = \operatorname{argmin}_{f \in \mathcal{F}} R_N(f)$
 - With regularization: $f_N = \operatorname{argmin}_{f \in \mathcal{F}} R_N(f) + \lambda ||f||^2$
- Our targets: We want to know how good f_N is
 - 1. $R(f_N) R_N(f_N) \le B(N, \mathcal{F})$: Estimate of the true risk of a trained classifier from its empirical risk
 - 2. $R(f_N) R(f^*) \le B(N, \mathcal{F})$: Estimate how far the true risk of a trained classifier from the best one

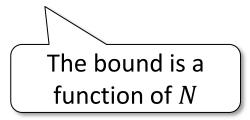

Error bound:

We want to give an error bound for a finite dataset

- Let us consider to find a bound $R(f_N) R_N(f_N) \le B(N, \mathcal{F})$
 - We want a bound depending on N

•
$$R(f) - R_N(f) = E[1_{f(x) \neq y}] - \frac{1}{N} \sum_{i=1}^{N} 1_{f(x^{(i)}) \neq y^{(i)}}$$

- By the law of large numbers, this will converge to 0
 - Empirical risk is a good estimate of the true risk
- $-\hspace{0.1cm}$ But we want to know $B(N,\mathcal{F})$ depending on a finite N

Hoeffding's inequality:

Bound of true risk for a fixed classifier

■ Hoeffding's inequality: Let $Z^{(1)}$, ..., $Z^{(N)}$ be N i.i.d. random variables with $Z \in [a,b]$. Then for all $\epsilon > 0$,

$$\Pr\left[\left| E[Z] - \frac{1}{N} \sum_{i=1}^{N} Z^{(i)} \right| > \epsilon \right] \le 2 \exp\left(-\frac{2N\epsilon^2}{(b-a)^2} \right)$$

- Gives the bound of probability of difference between expected value and empirical estimate exceeding ϵ
- For a classifier $f \in \mathcal{F}$, setting $Z = 1_{f(x) \neq y}$ gives $\Pr[|R(f) R_N(f)| > \epsilon] \le 2 \exp(-2N\epsilon^2) \equiv \delta$
- With probability at least 1δ , $R(f) R_N(f) \le \sqrt{\frac{\log_{\delta}^2}{2N}}$

Hoeffding's inequality: Simple application does not give the error bound

- For <u>a fixed</u> classifier f, its true risk is estimated by Hoeffding's inequality
 - With a fixed f, we can draw a sample with the bounded error with high probability
- But, this is not the estimate of the true risk of the algorithm
 - For a fixed sample, there are many classifiers in the pool that violate the bound, and the algorithm might find one of them
 - Before seeing the data, we do not know which classifier the algorithm will choose (this is not a random process), there is no guarantee the bound holds for the classifier
 - We want a bound which holds for <u>any</u> classifier f

Error bound:

Depends on the log number of possible classifiers

■ Theorem: With probability at least $1 - \delta$, $\forall f \in \mathcal{F}$

$$R(f) - R_N(f) \le \sqrt{\frac{\log|\mathcal{F}| + \log\frac{2}{\delta}}{2N}}$$

• This also implies: for $f_N = \operatorname{argmin}_{f \in \mathcal{F}} R_N(f)$,

$$R(f_N) - R_N(f_N) \le \sqrt{\frac{\log |\mathcal{F}| + \log \frac{2}{\delta}}{2N}}$$

- lacktriangle The bound depends on the number of functions in ${\mathcal F}$
 - $|\mathcal{F}|$: The size of the hypothesis space

Error bound:

Proof using the union bound

- We apply the Hoeffding's inequality to all classifiers in
 \mathcal{F} simultaneously
- Union bound:
 - For two events A_1 , A_2 , $Pr[A_1 \cup A_2]$ ≤ $Pr[A_1] + Pr[A_2]$
 - For K events, $\Pr[A_1 \cup \cdots \cup A_K] \leq \sum_{i=1}^K \Pr[A_K]$
- Hoeffding + union bound gives:
 - $\Pr[\exists f \in \mathcal{F}: |R(f) R_N(f)| > \epsilon] \le 2|\mathcal{F}| \exp(-2N\epsilon^2)$
 - Equate the right hand side to δ to obtain the upper bound

Sample complexity: Number of examples required to ensure a certain accuracy

■ Theorem: With probability at least $1 - \delta$, $\forall f \in \mathcal{F}$

$$R(f) - R_N(f) \le \sqrt{\frac{\log|\mathcal{F}| + \log\frac{2}{\delta}}{2N}}$$

This theorem means, in other words,

if we take
$$N \geq \frac{\log |\mathcal{F}| + \log_{\delta}^2}{2\epsilon^2}$$
 examples, with probability at least $1-\delta$,

$$R(f) - R_N(f) \le \epsilon$$

Error bound against the optimal classifier: Similar bound holds

- We are also interested in how far the true risk of a trained classifier from the best one in ${\mathcal F}$
 - $R(f_N) R(f^*) \le B(N, \mathcal{F})$
- Similar analysis gives a bound depending on $\log |\mathcal{F}|$
- Theorem: With probability at least 1δ ,

$$R(f_N) - R(f^*) \le 2\sqrt{\frac{\log|\mathcal{F}| + \log\frac{2}{\delta}}{2N}}$$

Our goal: How good is the classifier learned by empirical risk minimization?

- Unknown best function: $f^* = \operatorname{argmin}_{f \in \mathcal{F}} R(f)^{\stackrel{R: \text{true risk}}{=}}$
- Empirical risk minimization: $f_N = \operatorname{argmin}_{f \in \mathcal{F}} R_N(f)$
- We can know how good f_N is in two ways:
 - 1. $R(f_N) \leq R_N(f_N) + \sqrt{\frac{\log |\mathcal{F}| + \log^2 \delta}{2N}}$: Estimate of the true risk of a trained classifier from its empirical risk
 - 2. $R(f_N) R(f^*) \le 2\sqrt{\frac{\log |\mathcal{F}| + \log^2 \delta}{2N}}$: How far is the true risk of a trained classifier from the best one?

Infinite Case

Infinite case:

Previous results assume finite number of classifiers

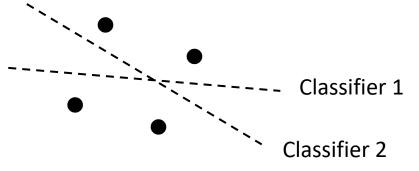

- We assumed the number of classifiers is finite
 - The bound depends on the number of classifiers in the

class
$$\mathcal{F}$$
: $R(f_N) - R_N(f_N) \le \sqrt{\frac{\log |\mathcal{F}| + \log^2 \delta}{2N}}$

- $\log |\mathcal{F}|$ is considered as the complexity of class \mathcal{F}
- So far we measure the complexity of the model using the number of possible classifiers (= size of hypothesis space)
- What if it is infinite? (E.g. linear classifiers $f = \mathbf{w}^{\mathsf{T}} \mathbf{x}$)
 - The upper bound goes to infinity ⁽³⁾
- Do we have another complexity measure?

Growth function: Infinite number of functions can be grouped into finite number of function groups

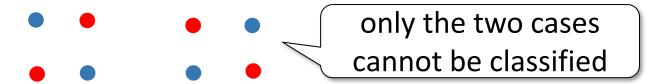

- For example, the class of the linear classifier has infinite number of functions
- Idea:
 - The following two classifiers make the same prediction for the four data points
 - They might be considered as the same for the purpose of classifying the four data points

Growth function:

Error bound using growth function

- Growth function $S_{\mathcal{F}}(N)$: The maximum number of ways into which N points can be classified by the function class \mathcal{F}
 - Apparently, $S_{\mathcal{F}}(N) \leq 2^N$
 - For two-dimensional linear classifiers, $\mathcal{S}_{\mathcal{F}}(4) = 14 \leq 2^4$

■ Theorem: With probability at least $1 - \delta$, $\forall f \in \mathcal{F}$

$$R(f) - R_N(f) \le 2\sqrt{2\frac{\log \mathcal{S}_{\mathcal{F}}(2N) + \log \frac{2}{\delta}}{N}}$$

VC dimension:

Intrinsic dimension of function class

- When $S_{\mathcal{F}}(N) = 2^N$, any classification of N points is possible (we say that \mathcal{F} shatters the set)
- VC dimension h of class \mathcal{F} : The largest N such that $\mathcal{S}_{\mathcal{F}}(N) = 2^N$
- For two-dimensional linear classifiers, h=3
- Generally, for d-dimensional linear classifiers, h=d+1
- Theorem: With probability at least 1δ , $\forall f \in \mathcal{F}$

$$R(f) - R_N(f) \le 2\sqrt{2\frac{h\log\frac{2eN}{h} + \log\frac{2}{\delta}}{N}}$$

Statistical learning theory: Theoretical guarantee for learning from limited data

- How many training instances are needed to achieve a particular test performance?
- What is the test performance of a classifier with a particular training performance?
- How far is a classifier from the best performance model?
